INTRODUCTION

The ovarian mass mostly has cystic form. The incidence of ovarian cyst was reported between 5 and 15 percent of all gynecological diseases.\(^1\)

Generally, the most common ovarian cysts is functional cyst, followed by endometriosis and dermoid cysts. Each type of cyst has its own characteristics so that we have to be careful in performing cystectomy to avoid the damage of ovaries. In women with ovarian cysts who undergo cystectomy, ovarian tissue damage may occur. It happens when normal tissue is removed due to the heat effect or cauterization process. Normal ovarian tissue should be maintained as much as possible because it is related to fertility condition signed by the ability of the ovaries to hold ovulation.\(^2\)

Anti-Mullerian Hormone (AMH) is a homodimeric glycoprotein sulfide bond to TGF-\(\beta\) group with molecular weight 140 kDa. It is a hormone that is produced by the granulosa cells of primary ovarian follicles and it plays a major role in the growth and differentiation of cells. The highest
expression is located in the follicular phase preantral and small antral follicles, and it will be no longer detectable when follicles undergo atresia. Level of serum AMH is strongly associated with the number of antral follicles. The AMH level describes the remaining of primordial follicles that reserved, which can be used as an illustration of ovulation induction success. The greater the ovarian tissue damage after cystectomy, the less number of normal follicles; thus, it will decrease AMH level after surgery.3

Ovarian reserve is a potential ovarian function that reflects the number and quality of remaining primordial follicles at such time. In the last two decades, serum AMH, Follicle Stimulating Hormone (FSH), Estradiol (E2), and inhibin B have been used as marker of ovarian reserve. However, inhibin B, FSH and E2 level fluctuate during the menstrual cycle; while, the level of serum AMH is relatively stable throughout the menstrual cycle. Therefore, AMH is better marker for predicting ovarian response than age, FSH, or inhibin B. A lot of studies used AMH as a marker of the ovarian reserve damage rate due to ovarian cystectomy.2

Measurement of serum AMH level is more easily performed than hyperstimulation of ovarian to predict ovarian reserve. It is stated that the change of ovarian reserve can be measured through serial measurement of serum AMH level which reflects the number of primordial follicles after ovarian surgery.4

Based on these ideas, we conducted a study which included all women with kinds of ovarian cysts undergo cystectomy surgery. The level of serum AMH on each type of cyst was measured before surgery, then repeated subsequently after surgery to determine the fluctuation of AMH level. Therefore, this study aims to investigate the comparison of the AMH as the ovarian reserve marker before and after cystectomy.

METHODS

This study was a prospective cohort design which was conducted in several teaching hospitals of Obstetrics and Gynecology Department, Faculty of Medicine Universitas Hasanuddin, Makassar from Desember 2014 to July 2015. The population was women with ovarium cyst exam in hospital. Subjects who met the criteria offered to participate in this study and they had to sign the informed consent. All blood samples were taken and examined in Nehri Laboratory of Universitas Hasanuddin Hospital. We processed the data using SPSS through one-way Anova, T-independent test, and T-paired test. Hypothesis testing was considered significantly if p<0.05

RESULTS

There were 40 subjects consisting of 21 patients with endometriosis cysts, 12 patients with functional cyst, and 7 patients with dermoid cyst. In this study, there was not difference in age, parity, body mass index, level of CA 125, and symmetry between endometriosis cysts, functional cysts, and dermoid cysts (p> 0.05) (Table 1).

Table 2 showed the average level of AMH before and after cystectomy on endometriosis also non-endometriosis cyst women. Before cystectomy through laparotomy, the mean of AMH level on endometriosis and non-endometriosis cyst group was 2.7 (SD 0.3) ng/ml and 3.1 (SD 0.4) ng/ml. The statistical test result using independent t-test showed there was difference in AMH level before cystectomy in patients with endometriosis and non-endometriosis cyst (p=0.001). The mean of AMH level after cystectomy was greater on both types (1.5 (SD 0.4) ng/ml and 2.4 (SD 0.4) ng/ml). Apart from that, the statistical result showed significantly different between groups (p<0.001).

Table 3 pointed out the mean level of AMH before and after cystectomy. There was a decrease trend of AMH level before and after cystectomy. The statistical test resulted the significant difference between this group (p<0.001).

**DISCUSSION**

The results of statistical test performed in this study showed the baseline characteristics of subjects were similar between groups so that these data would not influence the result of statistical test. Chang, et al. showed the decrease of AMH level one week after cystectomy and they found that AMH level would have recovery after 1 month and 3 months. The serum AMH level increased gradually after cystectomy and recovered about 65% after 3 months. There were several hypothesizes about the mechanism recovery of this AMH. Firstly, improvement of serum AMH level reflected the possibility of ovarian tissue reperfusion so that it released the AMH that normally produced by ovarian follicles group after forming the ovary blood vessel. Secondly, there was compensation in the form of hyperactivation on granulosa cells to produce the remaining follicle in ovary as the response of damage.
Although the number of follicles might decline after ovarian cystectomy, the amount of AMH secretion per follicle could be improved. Inflammation after surgery could stimulate ovarian follicle regeneration. Thirdly, some researchers speculated that the follicle could be saved from the follicle atresia.  

Study by Hirokawa and colleagues measured level of serum AMH before cystectomy and one month after laparoscopic cystectomy. They performed to 38 patients with endometrioma (20 unilateral and 18 bilateral). Serum AMH level significantly decreased after surgery. The decline in AMH level was found to correlate with bilateral cysts, not to diameter of cysts and age. Hirokawa, et al. also indicated the ovulation rate was significantly decreased in the ovary after cystectomy compared with before cystectomy.

The measurement of AMH level after surgery dropped significantly after cystectomy and it occurred greater on endometriosis cyst. On cystectomy, a decline of AMH level might happen due to the removal of ovarian parenchyma during excision of the cyst wall. According to Roman, it was commonly occurred because as histologically, there was no barrier between the fields lining of the cyst and ovarian cortex. Therefore, the operator had to estimate the excision of cyst wall so that it increased the risk of ovarian cortex damage which finally contributed to the reduction of ovarian reserve. In endometriosis cyst, there was no obvious barrier field due to fibrosis. This often led to accidentally remove number of ovarian cortex adjacent to the cyst wall and bleeding could occur in the hilum of the ovary; thus, the procedure required electrocauogulation that interfered with blood flow to the ovaries which were ended to reduce functional ovarian reserve. The decrease of serum AMH level was caused by accidentally removing of normal ovarian cortex, damaging due to coagulation electro surgery during hemostasis, or injury due to inflammation. All of them would result to healthy follicle loss.  

Cystectomy in endometriosis cyst caused more damage than the ovarian cystectomy on functional cyst. Removal of benign ovarian cyst would takeaway the ovarian tissue; however, this adverse effect was lighter than cystectomy in endometriosis cyst. Muzii, et al. hypothesized that this difference was caused by pseudocapsule in endometriosi cyst compared with clear capsule in non-endometriosis cysts in order to make separate fields and clear dissection area. Muzii, et al. showed the non-endometriosis cyst which had clear cyst wall (dermoid or functional cyst) resulted to normal ovarian tissue only in 6% of cases; while, in excision of endometriosis cyst, the normal ovarian tissue was found higher to 54% of cases.

Repair follicles may allow improvement of serum AMH level. It is because AMH is produced by the primary follicle, antral follicle, and small antral follicles. Developing follicles which are damaged after cystectomy will result to the lower level of serum AMH. Healthy primordial follicles are left behind because recruitment and growth of primordial follicle take time to produce AMH. Folliculogenesis from primordial follicles become prevulatory follicle about 85 days.

CONCLUSION

The decrease of AMH level is significant in the endometrial ovarian cyst women who undergo the cystectomy.

RECOMMENDATION

Further study in a serial and longer follow-up is needed to look the fluctuation trend of AMH level after cystectomy at 1, 3, and 6 months after procedure.
